Chapter 1

Introduction

This chapter presents the problem that the project tries to solve and describes the scope of the thesis. It also describes the document structure.

1.1 Introduction into the problem domain

In today's world information technology (IT) is present in almost every aspect of our lives. It is constantly being utilised by governments, military, organisations, financial institutions, universities and other businesses to process and store enormous amounts of data as well as transmit it between many computers around the globe. Any disruption to the work of those systems or unauthorized access to the stored information may result in significant losses. Those may include financial and geopolitical repercussions but also direct losses of human lives in situations where the target of an attack is for example a hospital. Since the inception and propagation of IT the security of the systems in question is growing concern of corporations, countries and even individuals. Because of the constant arms race between adversaries attacking and defending IT systems, anyone who is not proactively handling matters concerning cyber security is instantly falling behind. [17]

A typical attack on an IT system may include exploitation of a design flaw to gain increased access. The offensive actions can target many different layers of abstraction present in current IT systems. Such situations are extremely hard to discover and guard against due to the fact that they were not foreseen in the design

process. How to guard against something that is not known to be possible. There are many approaches that aim to increase the security of IT systems. Some popular ones include fingerprinting malware, monitoring software for specific suspicious actions or monitoring software inputs for known malicious values. Those approaches can be very effective but failures are inevitable.

To mitigate this problem multiple studies have been done that attempt to utilise the methods of anomaly detection known from the data science fields in order to identify the misbehaviours of the monitored IT systems which could allow for an early detection of novel 0-day based intrusions. The past investigations of the problem have focused on analysis of the information obtained from multiple sources like system commands sequences [20] or system calls [18]. There are however still many mechanisms present in modern operating systems that gather significant quantities of information about inner workings of the processes executed on them.

The objective of this thesis is to utilise the Event Trace for Windows (ETW) mechanism and its capability to access low level debugging data on the Microsoft operating systems to attempt security anomaly detection. The main focus is placed on identification of 0-day binary process exploitation leading directly to arbitrary code execution. While taken under consideration in light of gathered information, other attack types like for example DLL hijacking are not in scope of this work.

1.2 Authors contribution

Author of the thesis has simulated a 0-day exploitation attack on a web browser and gathered the data generated in the process via the Event Trace for Windows mechanism. This process required establishing of the information gathering framework. The acquired information was processed to identify and extract features that could be utilised in an anomaly detection methods. This procedure included developing some novel data encoding approaches. Gathered data was tested with known classification algorithms and the results of the experiments were analysed. Based on the performed actions a conclusion was formed about the usefulness of the ETW data in potential anomaly detection based security system. Additionally further research directions have been established.

1.3 Chapters description

This thesis is constructed with following chapters.

- Introduction - Describes the domain of the researched problem and the basis for the topic of the thesis. Highlights the the contributions of the author. Provides overview of the chapters present in this document.
- Problem analysis - Theoretical indepth study of the work required to achive the thesis goal. Investigation of known literature related to the researched topic. Description of the previous known solutions of the problem.
- Security anomaly detection based on Windows Event Trace - Full description of the proposed solutions and their theoretical analysis. Rationalization of the employed algorithms, methods and tools.
- Data gathering - Thorough explanation of the performed data gathering process and of the obtained results.
- Experiments - Full description of all experiments performed in the process of thesis research. Analysis of the outcomes.
- Summary - Synopsis of the performed work. Summary of all the resulting conclusions and possible future research directions. Analysis of the thesis goal in light of the obtained results.

Chapter 2

Problem analysis

This chapter is a indepth overview of the problem related information available in the public litelature and resources. Additionally it contains analysis of complications possibly encountered durring the realisation the required work.

2.1 (

Known problems) There are multiple problems that need to be solved to form conclusions to the stated questions. There are no commonly available security focused datasets sourced from the Event Trace for Windows mechanism. The data used in the thests has to be generated and gathered as part of the performed work. The information processed by the ETW is very broad and can be additionally extended. A analysis has to be done in order to identify the features that can prove useful in the security anomaly detection scenarios.

Gathered data might require preprocessing that will adjust it's form to the formats accepted in the current classification methods and algorithms. Some types of information present in the computer generated data set might require utilisation of novel processing and encoding frameworks or development of new approaches to them.

2.2 Literature research

The previous attempts of implementing a security anomaly detection frameworks depicted in the literature take many different approaches. Some of those include analysis of specific sequences present in terminal commands [20] or system calls [15].

Some researchers attempt to implement novel custom classification methods. An example of such approach is depicted in "An Application of Machine Learning to Anomaly Detection" by Terran Lane and Carla E. Brodley[20]. The authors gather historical sequences of terminal commands and their corresponding utilised command flags. The obtained vectors are utilised to calculate similarity measures with the incoming data. Those values are utilised to identify whether the user interacting with the system was previously profiled by the algorithm. Other approaches classify available data with well known algorithms like various Support Vector Machines (SVM) and K-means like Wenjie Hue, Yihua Liao and V Rao Vemuri in "Robust Support Vector Machines for Anomaly Detection in Computer Security" [18]. Their work compares the performance of Robust Support Vector Machines (RSVM), Support Vector Machines and K-means classifiers on the data from 1998 DARPA Intrusion Detection System Evaluation program. Obtained results prove the superiority of RSVM's in the tested use cases. Some researchers try to perform security data classification with novel anomaly detection methods like autoencoders. This approach was attempted for example in "Anomaly Detection on the Edge" by Joseph Schneible and Alex Lu [24]. This method learns to compress and decompress the available feature vectors with the use of artificial neural vectors. Anomaly is detected when the distance between the input and output of the neural net is higher than the specified threshold.

Chapter 3

Security anomaly detection based on Windows Event Trace

This chapter contains indepth description of the solutions proposed for the thesis problems.

3.1 Data gathering

To achieve the goal of the thesis a dataset based of the Windows Event Trace has to be created. The ETW framework can be accessed and utilised via API available in multiple programing languages like C/C++[6] or C#[5]. The data gathering process should however be performed with known and tested solutions to minimise the chance of data corruption. The default file format used by ETW for storing information is a Event Trace Log (ETL). This archive type is not very well documented in the resources available on the internet. A additional tool might be required in order to transform gathered information to commonly known data storing formats.

Event Trace for Windows handles very granular process and operating system events. Because of that when configured to gather all possible types of information ETW can generate large quantities of information. Additionally known tools gather data in rotating memory buffer before saving it to hard drive. Those two factors combined with limited memory resources available while performing the

data gathering process limit the types of information analysed in the thesis.

3.2 Analysed data

Available information has been narrowed down to following features analysed to achieve the thesis goal.

3.2.1 Dynamic link libraries

When attempting to detect misbehaviour of a specific program or its subprocesses a possibility to classify binaries by their general purposes could prove very useful. Most methodologies used to compare executable files focus on their binary structures and attempt to find similarities to existing malware samples [19]. This approach, while very useful in detection of iterations of malicious software, is useless when it comes to creating multidimensional spaces based on their functionality. In this thesis an attempt is made to utilise a novel approach of analysing the processes by their imported Dynamically Linked Libraries. A DLL is a library that contains code and data that can be used by more than one program at the same time. For example, in Windows operating systems, the Comdlg32 DLL performs common dialog box related functions. Each program can use the functionality that is contained in this DLL to implement an Open dialog box. It helps promote code reuse and efficient memory usage [3]. Those code bundles provide specific sets of functionality and are commonly used in all programming languages. Possibly overlapping sets of loaded modules from two given processes can indicate their similar purpose.

3.2.2 Subprocess paths

Initial empirical analysis of the impact of the exploit on the behavior of the targeted browser was performed with the use of Windows Performance Analyzer (WPA). Most browsers give a possibility of spawning a new process for example by opening of a downloaded file in adequate software. This makes it harder to detect when it is exploited. However upon closer look on the way that action is performed

Figure 3.1: Example process tree of Microsoft Edge

we can see that proper child process is spawned from the main browser process.

The exploit however generates a new child from the one corresponding to the browser tab in which the exploit was executed.

Patterns like this might be possible to learn and detect. The obtained data can be transformed to create a new feature called "Process Path". It is a string based variable containing names of the consecutive child processes starting from the root of the system process tree leading to the process for which the feature is constructed. All names are divided by any arbitrary separator.

Encoding of such variables like directory paths is not a well researched topic and there is no common consensus on how they should be approached. There are however some novel approaches to handling dirty categorical data. An example of how to handle data like that was featured in the "Similarity encoding for learning with dirty categorical variables" by Patricio Cerda, Gaël Varoquaux and Balázs Kégl. Where in most literature on encoding categorical variables relies on the idea that the set of categories is finite, known a priori, and composed of mutually exclusive elements, the authors of this paper propose a new approach called similarity encoding. It is based on calculation of similarities between string values. Instead of a binary column indicating whether a specific category was set in the input value, a real number indicates how distant it is from the specific previously

chosen encoding column. It is a generalisation of the OneHot method [14]. The python implementation of this approach utilised in this thesis can be found under <https://dirty-cat.github.io/stable/>.

3.2.3 Average processor utilisation

This feature represents how processor intensive the given process is. This information can possibly be utilised both the processes that are not usually spawned by the one being analysed as well as inlier processes that missbehave due to the performed exploitation. Because this feature is strictly numerical, it is a lot easier to analyze than the qualitative values like the process paths and the loaded DLL's. It is also a lot less impacted by the actions of the normal user when compared to the process lifespan values from which it is derived.

3.3 Anomaly detection algorithms

In the thesis the main anomaly detection algorithm utilised is the One Class Support Vector Machine which is a variation on support vector machine. It attempts to minimise the radius of the multidimensional hypersphere with the use of Kernel Method [25]. This algorithm is the main anomaly detection utilised in the thesis due to it's ease of usage. It is also known to be effective in high dimensional spaces and when the number of features is greater then the number of samples [10]. The training process does not require significant computational and memory resources when compared to the latest approaches based on artificial neural networks like autoencoders [13]. There are some approaches to training the can be less demanding in example the distributed architecture [24]. Their complexity might however shift the focus from the core idea of the thesis which is to prove that Windows Event Trace can be utilised to detect security anomalies. In the thesis the detection performed by the One Class SVM is tested for multiple 'nu' values which is upper bound on the fraction of training errors and a lower bound of the fraction of support vectors[9]. The kernel utilised in all the tests is 'rbf' with the gamma parameter set to 'auto'. The detection process is performed on a per process basis and focuses mainly on the web browser Microsoft Edge.

For all anomaly detections performed in the research following parameters were quantified:

- Positive (P) - number of samples correctly classified as inliers.
- Negative (N) - number of samples correctly classified as outliers.
- False positive (FP) - number of samples misclassified as inliers.
- False negative (FN) - number of samples misclassified as outliers.

Those values may be also expressed in percentages. Detection accuracy for example is the ratio of detected anomalies (Negative) to all marked in the dataset. False positive probability is the number of misclassified samples (False negative) divided by the known count of inliers.

Based on the studied literature one of the well-suited result presentation methods is the Receiver Operating Characteristic (ROC) curve which is a plot of the detection accuracy against the false positive ratio. In this document the detected outliers are classified as negative samples. Because of that the receiver operating characteristic curves are plotted as true negative ratio against the false negative. The probability of false anomaly detection is crucial because it may cause overload on of the response teams and mechanisms which in turn may result in delayed response or omission of actual exploitation. All anomaly detection performance analysis in the thesis is focused on those indicators. The ROC curves may however be corrupted by the small available sample size which negatively impacts the performance analysis.

Chapter 4

Data gathering

This chapter describes the process of gathering data utilised in the experiments and analysed in this thesis. This procedure is necessary due to the lack of commonly available datasets that would fit the requirements of the work that had to be performed.

4.1 Exploit emulation

The data used in the thesis was gathered on a Windows 10 Enterprise Evaluation operating system, version 20H2, build 19042.1052. The Microsoft Edge web browser used to simulate the 0-day exploit attack was artificially halted in the version 84.0.522.52 (64-bit). Automatic updates were interrupted by changing the name of the binary responsible for keeping the software up to date. It is commonly located under "C:\Program Files (x86)\Microsoft\EdgeUpdate\MicrosoftEdgeUpdate.exe". The attack simulated in the data takes advantage of the vulnerability CVE-2021-21224. It targets a type confusion flaw in the V8 JavaScript engine. This allows the attacker to execute arbitrary code inside a sandbox via a specially crafted HTML page [1]. The vulnerability affects the Google Chrome browser prior to the version 90.0.4430.85 as well as Microsoft Edge prior to 90.0.818.41 [4]. Some reports indicate that this vulnerability might have been used by the state backed north korean agents to attack security researchers and gain insight into their work. The exact method of exploitation is not known since the abuse of CVE-2021-21224 does not

not allow to bypass the builtin Chromium sandbox. There are also reports of Russian government-backed actors using CVE-2021-1879 to target western european government officials [21]. This method might have been chained with other non-public vulnerabilities in order to perform a successful attack. To simulate such conditions the browser used in testing was run with the `"-no-sandbox"` flag which disables the builtin safeguard.

The sample of the exploit code was obtained from a public GitHub repository [16] and it's code can be found in the listing `"exploit.html"`. It was adjusted to result in the start of the PowerShell.exe process. Execution of this cross-platform task automation solution made up of a command-line shell, a scripting language, and a configuration management framework is usually one of the first steps in the process of gaining persistent access to a given machine. Some actors implement advanced code and logic into the exploit. This is however very uncommon due to the high complexity of such a task.

All the information was gathered in a context of a single user due to restricted available resources and to simplify the task of anomaly detection. Fullfilling the goal of the thesis even in those conditions can be a viable proof of concept which would warrant further research in wider domain.

4.2 Logging

The initial data was gathered by the PerfView.exe tool which is "a free performance-analysis tool that helps isolate CPU and memory-related performance issues. It is a Windows tool, but it also has some support for analyzing data collected on Linux machines. It works for a wide variety of scenarios, but has a number of special features for investigating performance issues in code written for the .NET runtime"[22]. It is capable of tapping into many ETW logging sessions and storing the gathered data into output files. It also has functionality that helps in working with the saved information. Main purpose of PerfView in the thesis was data gathering and preprocessing. The software is open source. It was configured to gather only the "Kernel Base" information. The additional data sources were disabled due to the large quantity of data being generated and not sufficient memory available for the processing. Example PerfView configuration can be found in figure 4.1.

Figure 4.1: Example PerfView logging configuration

The resulting information is saved to a Microsoft Event Trace Log File (.etl) which can be processed in multiple ways. PerfView has a builtin function of extracting the information gathered about the executed processes and their loaded dll's to Excel executable installed on the system. This can be performed by opening the desired file in the builtin explorer and selecting its "Processes" option. This opens a separate window containing information about processes executed during data gathering and two possible export options - "View Process Data in Excel" and "View Process Modules in Excel". The Excel executable opened by choosing either of the options allows to save the data to multiple easily accessible file formats like .csv, .xml or.xlsx. Loaded data and the export options are presented in figure 4.2.

Resulting from the described process are two files containing correlated information. By default Excel labels those files by including identifying suffixes in their names. The first file is marked by the string "processesSummary" and contains general information about the processes which include following columns:

- Name - Process name - The name of the process, usually identical to the

Figure 4.2: PerfView data export

binary file name.

- ID - Process Id - The integer number used by the kernel to uniquely identify an active process [23].
- Parent_ID - Parent Process Id - The Process Id of the process that spawned the correlating one.
- Bitness - Whether the process executable is created in 32 or 64 bit architecture.
- CPUMsec - Amount of milliseconds in which the process has occupied the processor.
- AveProcsUsed - Average processor utilisation calculated by dividing the amount of time when process has occupied the processor by the total process lifespan.
- DurationMSec - The duration of the process life stored in milliseconds.
- StartMSec - The start time of the process stored in milliseconds.
- ExitCode - Integer value returned after the process execution. Commonly known as exit code.
- CommandLine - The command used to spawn the process.

Second output file commonly contains the string "processesModule" in its name. Its contents are the modules (DLL's) loaded by a specific process and information about them. Example output file contains following data columns:

- ProcessName - Name of the process which loaded the corresponding DLL
- ProcessID - Id of the process which loaded the corresponding DLL
- Name - Name of the loaded DLL
- FileVersion - Version of the loaded DLL
- BuildTime - Date when the DLL file was build

- FilePath - The location of the DLL file on the host system

Data gathering was performed on a simulated host usage to acquire inlier data samples required for the algorithm training process. The tasks performed in the process included consumption of online media (eg. youtube.com, netflix.com), office work on cloud based services (eg. Google Docs, Gmail), social media browsing (eg. facebook.com, twitter.com), downloading files and other web browsing. Downloaded files were opened directly from the browser. The data was gathered on the span of multiple user sessions.

4.3 Preprocessing

Gathered data was initially analysed and processed to fit different machine learning frameworks and to simplify its manual analysis. This operation was complicated by the reuse of process id's in the operating system. In order to identify which of the processes corresponding to the parent id is the true ancestor a additional check is performed based on the time of spawn and the interval in which the possible parent was alive. This algorithm allows the creation of a spawning process path that tracks the ancestors of a given process, usually to one of multiple root programs in the operating system.

Additionally a process of OneHot encoding was performed on the loaded DLL's. The data from the "processSummary" and "processModules" files was correlated by the order in which it was stored. Similarly as before this approach was chosen because of the reuse of process id's. Three of the stored processes never in testing had any corresponding modules - "Registry", "MemCompression" and the process marked with -1 ProcessId. Obtained data was additionally validated with the input information to minimise the risk of introducing error to the dataset.

The final product of the data processing is a dataset containing information about all the executed processes. Each row represents an individual process and following information is provided in the columns:

- ProcName - Process name - The name of the process, usually identical to the binary file name.

-
- ProcId - Process Id - The integer number used by the kernel to uniquely identify an active process [23].
 - ProcPath - String containing sequence of parent processes separated by "/".
 - ProcPathId - String containing sequence of parent process id's separated by "/".
 - CommandLine - String containing the shell command used to start the process.
 - ParentId - The identifying integer number of the parent process.
 - DLLs - All columns not listed above contain OneHot encoded information about the dynamically linked libraries. When a column contains value 1 the process has loaded the dll specified in the column name.

Chapter 5

Experiments

This chapter describes the experiments performed to achieve the purpose of the thesis and the underlying methodology. This includes the utilised tools, information about used datasets, description of the taken actions and presentation as well as analysis of the obtained results.

5.1 Methodology

Experiments performed to achieve the goals of the thesis were executed with the use of the Python 3.8.3rc1 programming language. It was executed via the Jupyter framework which is a is "an open-source web application that allows you to create and share documents that contain live code, equations, visualizations and narrative text. Uses include: data cleaning and transformation, numerical simulation, statistical modeling, data visualization, machine learning, and much more" [7]. Each experiment was performed in a separate Jupyter notebook and obtained results were analysed in the same framework.

Gathered data was also analysed in the Windows Performance Analyzer (WPA) which "is a tool that creates graphs and data tables of Event Tracing for Windows (ETW) events that are recorded by Windows Performance Recorder (WPR) or Xperf. WPA can open any event trace log (ETL) file for analysis" [11]. This software was used to perform initial analysis of the 0-day exploitation of the chromium based browsers and to formulate areas of focus in the gathered data. The tool can be

easily installed on Microsoft Windows operating systems from the Microsoft Store.

5.2 Data sets

Main dataset utilised in the thesis is called

Data is stored in a CSV format which is a text based file for tabular information. Each entry in the file is separated by the new line character and its features are divided by commas. This simple, non-proprietary format is very accessible and supported by most known data handling programs and frameworks.

The dataset was acquired in 4 user sessions. In one of those a simulated 0-day attack was performed. The processes spawned in result have been marked as anomalies.

After preprocessing of the data following features are stored in the output file:

- Session - String identifier of the session in which the corresponding process data was gathered.
- ID - The integer number used by the kernel to uniquely identify an active process.
- Name - The name of the process, usually identical to the binary file name. Expressed by a string data type.
- Path - String containing sequence of parent processes names separated by "/".
- PathId - String containing sequence of parent processes id's separated by "/".
- CommandLine - String containing the shell command used to start the process.
- ParentID - The identifying integer number of the parent process.
- CPUMsec - Amount of milliseconds in which the process has occupied the processor. Integer value.

- AveProcsUsed - Average processor utilisation calculated by dividing the amount of time when a process has occupied the processor by the total process lifespan. Expressed in floating point numbers. This value is derivative combination of the features "CPUMsec" and "DurationMSec" but it is still stored for verification purposes.
- Bitness - Integer value indicating whether the process executable is created in 32 or 64 bit architecture.
- DurationMSec - The duration of the process life stored in milliseconds. Expressed in floating point numbers.
- StartMSec - The start time of the process stored in milliseconds. Expressed in floating point numbers.
- ExitCode - Integer value returned after the process execution. Commonly known as exit code.
- Y - This binary column indicates whether the corresponding entry is an anomaly. Value "1" corresponds to inliers and "-1" to outliers. Processes marked as "-1" were spawned as a result of 0-day exploitation.
- The remaining columns contain OneHot encoded information about the dynamically linked libraries. When a column contains value 1 the process has loaded the dll specified in the column name. Otherwise the column contains 0. Full list of the captured modules can be found in the appendix

The dataset utilised in the thesis can be found in a public repository

5.3 Results

In all of the experiments performed the focus was placed on 'msedge' binary and its child processes. The dataset was filtered with the use of 'ProcessPath' feature. Any string value containing the 'msedge' substring indicated that the corresponding process is either Microsoft Edge browser or was spawned by it.

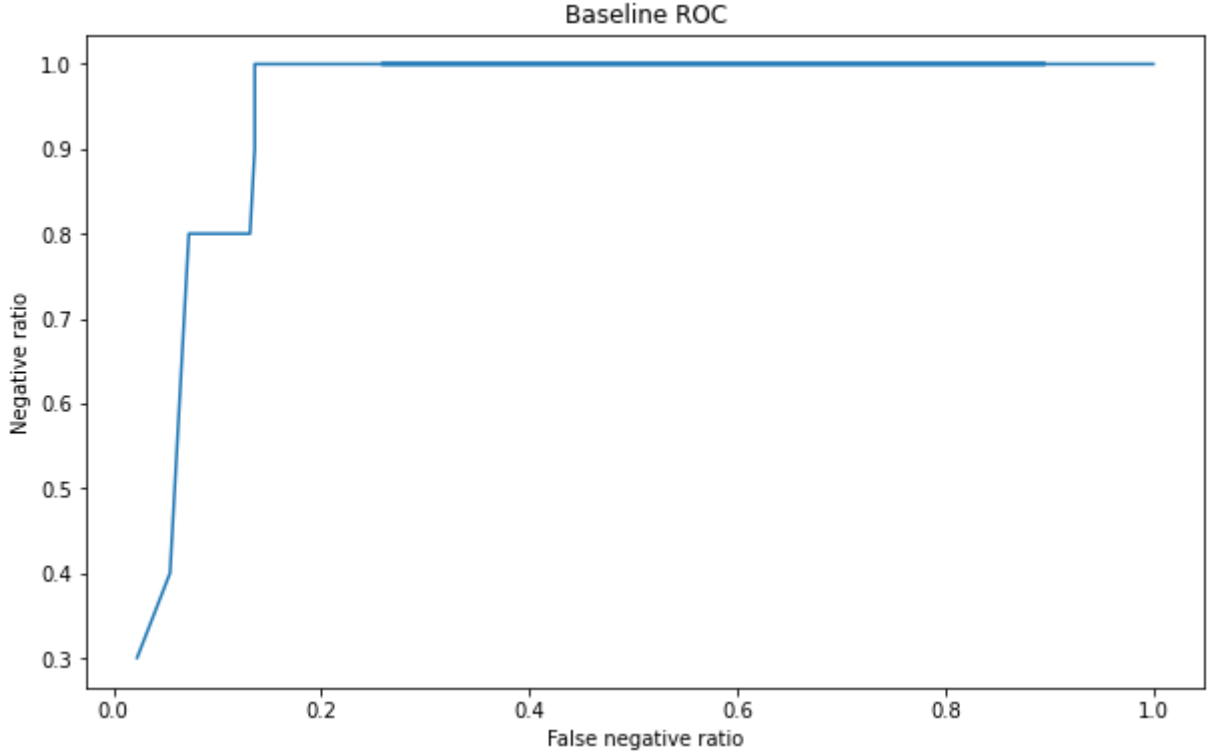

Figure 5.1: The receiver operating characteristic of the baseline anomaly detection.

5.3.1 Dynamic link libraries

To obtain baseline results to which any developed frameworks can be compared a one class SVM anomaly detection was performed on the raw one hot encoded DLL data. The results of this process can be found in the figure 5.1 and show that singling out of the outliers is possible with this type of information. The raw results can be found in the table 1 located in the appendix.

In the initial analysis of the data we can look at the counts of DLL's loaded by specific processes. The distribution of those values can be found in the histogram 5.2. From depiction we can clearly see that some of the outlier samples lie distant from other samples. This pattern may be detectable.

To test the hypothesis the DLL counts were normalised to fit the range from 0 to 1 and a anomaly detection was performed. The ROC of the process is visible in the figure 5.3 and raw outputs are presented in the table 2. Both of those show

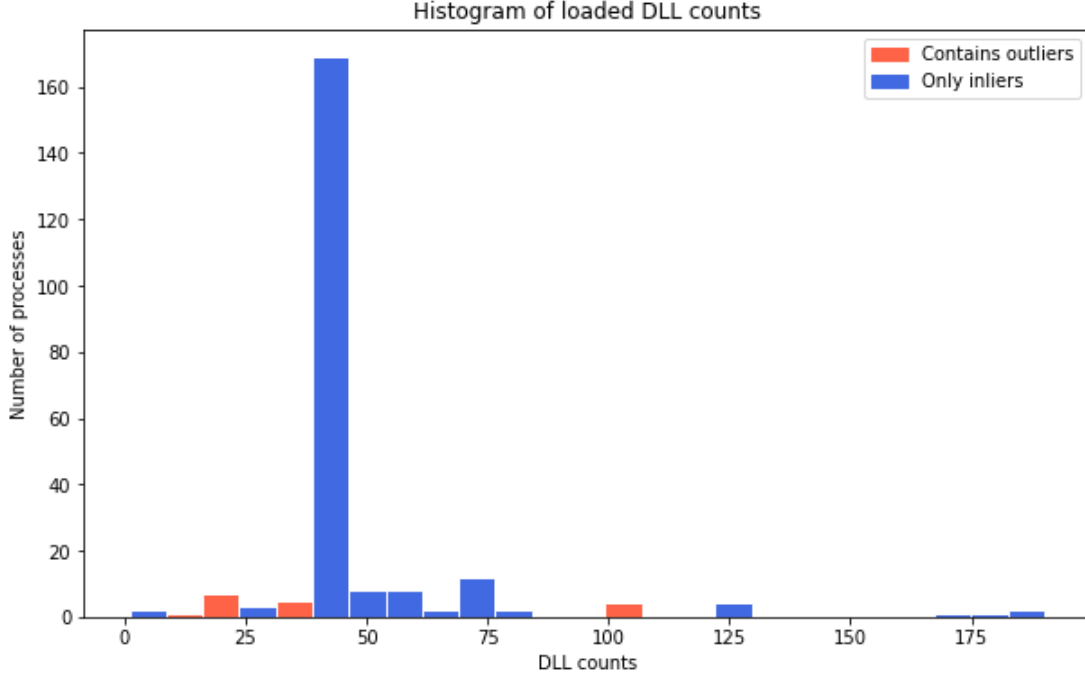

Figure 5.2: Histogram of the counts of DLL's loaded by processes.

that negative samples were at least partially correctly labeled for some classifier configurations. In some cases 100% of anomalies was detected with a relatively low false negative ratio.

There are over 1400 different DLL's gathered in the data set created. A single process loads even upto 287 modules. This extremely high dimensionality of the information might be too complex to analyse efficiently, even for the algorithms that can handle well datasets where features outnumber samples. To better understand the gathered information a multiple component analysis (MCA) was performed. This extension of correspondance analysis allows us to analyze the pattern of relationships of multiple categorical dependent variables [12]. It was performed with a python mca 1.0.3 library [8]. The result of this process is a set of points in a low-dimensional map corresponding either to columns or rows of the input data frame. Their distance in the obtained space can be used to classify how strongly they are correlated with each other.

The principal inertias (eigenvalues) obtained as the result of the algorithm can help us better understand how well the resulting dimentions express the relations

Figure 5.3: The receiver operating characteristic of the baseline anomaly detection.

Figure 5.4: Multiple correspondence analysis inertias.

between the input samples. The values calculated were normalised and can be found in the figure 5.4 and the table 3 located in the appendix. Those results suggest that the usefulness of the dimentions in the data analysis significantly drops after the first one. The two following values are however very similar which indicatetes that it might be good to adjust the dimention cutoff to utilise only the first one or all three.

To validate that the MCA can extract viable information from the available data, it's results for all the processes were compared to the actual purpose for each 'msedge' subprocess. The location of the binaries in the obtained multidimensional space can be found in the figures 5.5 which depicts dimentions 0 and 1 as well as figure 5.6 for dimentions 1 and 2. The raw numerical values utilised to generate those visualizations are located in the table 4 placed in the appendix of this document.

From the distributions we can clearly see that MCA process has managed to group closely identical processes. It is also very apprent that the outlier 'powershell' is significantly distant from all remaining samples. This pattern can be spotted in

Figure 5.5: Multiple correspondance analysis distribution in the first and second dimation.

Figure 5.6: Multiple correspondance analysis distribution in the second and third dimation.

both figure 5.5 and 5.6. Those results are very promising and indicate that at least partial detection of anomalies is possible and the peak performance has improved when compared to the raw data baseline.

Additionally to this strategy a simple anomaly detector based on the detection of any previously not loaded DLL can be utilised. This method could be a solid intrusion detection system on its own and it's performance would not be dependent on the proper adjustment of parameters as in the more sophisticated approaches. The DLL's present only in the outliers can be found in table 5.1.

The proof of possible classification is illustrated in the figure 5.7 which shows the results One Class Support Vector Machine anomaly detection performed directly on the first two dimensions of the data from multiple component analysis. The raw data used to obtain the ROC can be found in the table 6 located in the appendix. With proper configuration the algorithm has managed to detect two anomalies with zero false negative results. This approach however is very difficult to apply in the production environment due to the full dataset required prior to classification. This data may be however utilised to develop and train a custom encoder capable of positioning the new input data in the previously analysed DLL space.

The idea behind the custom encoder is to group DLL's by their common occurrence and therefore conclude common functionality of the programs that share them. This task can be performed with the use of unsupervised classification algorithm like K-means with N classes on the results of the MCA performed for the columns of the inliers. Example of such classification performed for four classes is showed in the figure 5.8. The resulting O_i sets of unique DLL's, each set of the size S_i where $i \in \{1, 2, 3, \dots, N\}$ can be utilised to create a vector F_j of $j \in \{1, 2, 3, \dots, N + 1\}$ features for any new data sample X where X .

$$x_i = \sum \quad (5.1)$$

The encoder can be adjusted with parameters like the number of classes in the unsupervised classifier as well as the number of dimensions utilised from the multiple component analysis. This approach combines the detection of previously unknown DLL's with the attempt to dynamically assign specific DLL's to groups by their location in the MCA space.

Figure 5.7: ROC curve of OCSVM directly on MCA data

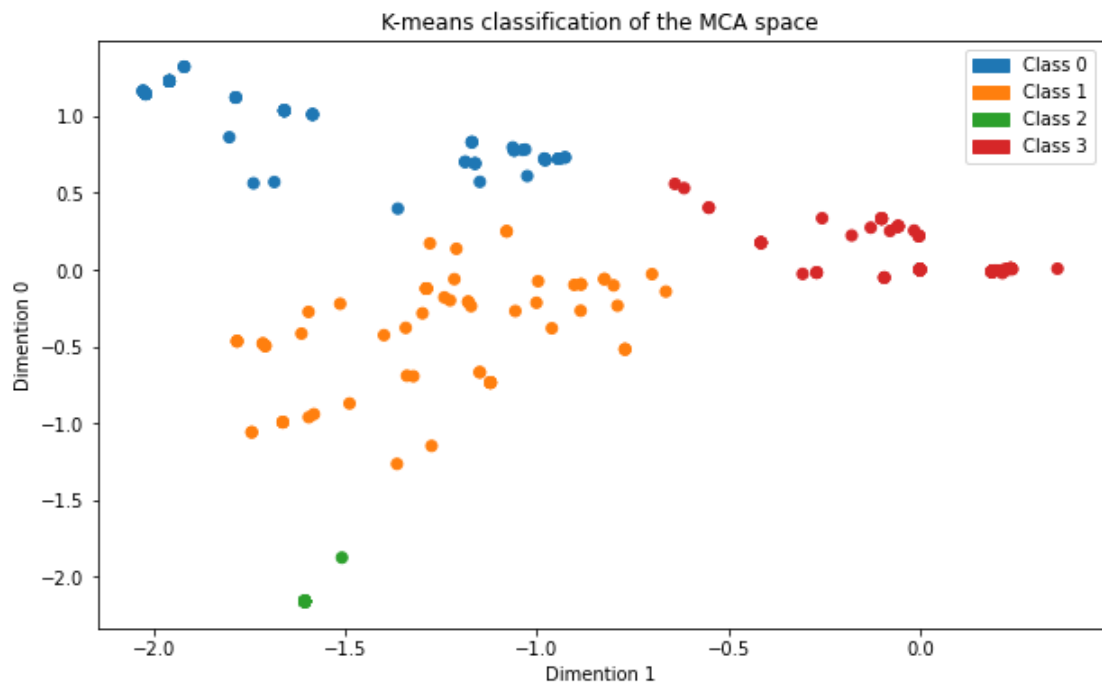

Figure 5.8: Unsupervised classification of MCA results

All 'msedge' samples were tested on the on the encoder trained only with the inlier samples. This solution was tested for multiple sets of possible parameters. The number of utilised MCA dimentions was equal 3 as in the detection performed directly on the MCA data. This was done to allow for just comparison of the results. The anomaly detection was performed both with and without the last dimention corresponding to the occurance of previously unknown DLL's. The results of this experiment are presented in the table 5.2. The stored values are sorted by the number of 'Negative' detections descending and 'False negative' ascending. The table contains following additional columns:

- clusters - Number of clusters resulting from K-means classification.
- other_c - The increment coefficient for DLL's not grouped in the K-means stage.
- New_DLL - A True/False value indicating whether the dimention corresponding to the previously unknown DLL's in the encoded feature vector was utilised in the classification.

Those results show that the classification performed on the encoded data can be as efective as the one performed directly on the MCA data. It can also outperform it in the number of correctly labled negative samples with a smaler increase in false negative increase. The anomaly detection was most accurate in the negative sample detection for the number of clusters equal to 1. The additive nature of the encoder means that in those cases the detection is actually performed on the DLL counts. This configuration also most efective when the primary focus is on the reduction of the false negative amount. The increase of dimentions can however lead to higher number of detected negative samples with low rise in the mislabeling. The performance is best when the dimention responsible for new DLL's is taken under account in classification it can however work even without it.

The encoder was also tested with the training data unlabeled data. All samples were fed in the classification phase. The obtained performance was comparable to the one of the encoder trained only on the inlier samples but with different sets of input parameters. Obtained values can be found in the table xxx.

Table 5.2: Classification with new encoder.

The performance of the develop methot should be tested on the completely separate validation data but the gathered data set is very small and to best perform this task an additional samples should be gathered in the future work.

5.3.2 Process paths

We can see in our data that some paths contain the "msedge" parent process and some start with the first edge browser. This may be a result of a specific case in the data gathering process or the result of wrong processing. In the future some logs may contain even more complex prefixes to the actually investigated process. For those reasons the first step in the process path analysis should be their normalisation which would result in them starting with the process of intrest in the first place. In our dataset this can be achieved by cutting off any prefix values before the first "msedge".

All paths corresponding to the researched process consist of elements presented in the table 5.3. The unique values obtained after normalisation are presented in the table ???. The full list normalised paths can be found in the appendix 5.

This data cannot be fed directly to the classification algorithm because of it's qualitative nature. Because of that no baseline can be obtained. The basic feature of the path it's size - the number of processes contained in it. The distribution of the path lengths is presented in the graph 5.9. Those values extracted can be scaled and used to detect anomalies.

Those values extracted can be scaled and used to detect anomalies and the per-

Figure 5.9: Histogram of the path lengths.

formance of this approach is depicted in the table xxx. Obtained values show that outliers can be detected with a manageable false positive ratio. This is especially visible in the row 4 for 'nu' values equal to 0.05.

In order to attempt recognition of more complex patterns in the data it was encoded with the use of a Similarity Encoder which assigns values to the input based on its similarity to the known char strings obtained in the training process. The outputs are calculated with one the available algorithms like "N -gram", "Levenshtein-ratio" and other. This encoder is capable of handling previously unknown values which is a big factor when processing qualitative features like paths. In a cases where new values occur in the data processing, classic encoders like "OneHot" fail.

In the initial approach the paths were normalised to start with the same initial 'msedge' process and split on the separators to obtain a matrix of their components. Each entry in the matrix corresponds to a single path and the columns represent segments in the path. The matrix width is equal to the maximum path length in the data where path length is equal to the number of components from which it is build. Paths shorter than matrix width were padded in the splitting process with empty strings. The result of this process is presented in the table xxx located in the appendix.

The encoder trained with the inlier split data assigned known entries to each column and this information was used to encode all samples which subsequently were analysed with the One Class SVM. The results presented in the table xxx show that this approach is very ineffective.

The results of the anomaly detection performed with the 'nu' value equal to x were inspected to establish the root causes of the low performance. The first noticable problem with the data is the handling of the empty string values. The similarities for each input column are calculated to the corresponding set of know values which result in multiple encoded values per column. Because of that the returned result is flattened to the vector form in which entries correspond to both the input dimension and it's specific categories.

An example of this can be shown with the following categories based on the ones computed for the the used data:

- Column 1 - "", 'cpu-z_1.96-en', 'msedge', 'notepad'.
- Column 2 - "", 'cpu-z_1.96-en', 'msedge'.

Those result in the output vector with following entries:

- Similarity of the first column entry to the "".
- Similarity of the first column entry to the 'cpu-z_1.96-en'.
- Similarity of the first column entry to the 'msedge'.
- Similarity of the first column entry to the 'notepad'.
- Similarity of the second column entry to the "".
- Similarity of the second column entry to the 'cpu-z_1.96-en'.
- Similarity of the second column entry to the 'msedge'.

In our data the the similarities to empty strings (") is always equal to zero, even if the input is identical. This is most probably due to the limitations in the utilised string comparison algorithms. Because of that our calculated categories:

```
[
    ['msedge'],
    ['', 'cpu-z_1.96-en', 'msedge', 'notepad'],
    ['', 'cpu-z_1.96-en', 'msedge'],
    ['', 'cpu-z_1.96-en', 'notepad'],
    ['', 'cpu-z_1.96-en']
]
```

are in reality:

```
[
    ['msedge'],
    ['cpu-z_1.96-en', 'msedge', 'notepad'],
    ['cpu-z_1.96-en', 'msedge'],
    ['cpu-z_1.96-en', 'notepad'],
    ['cpu-z_1.96-en']
]
```

Additionally it is possible that because the encoder was designed to be more robust in the face data variance, in other words smooth out anomalies. Even though this process allows for the handling of new values it might significantly disrupt anomaly detection.

An example of this is the process `'/msedge/msedge/powershell'` which is a clear outlier but in the encoded form it is equal $[1., 0., 1., 0., 0., 0., 0., 0.]$. This is equal to the 'center of gravity' of the encoded data because the by far most numerous process `'/msedge/msedge'` obtains the same value. This is due to the third element of the outlier process path having no similarity of the known previous values.

On the other side of the spectrum is the inlier `'/msedge/notepad'` value which encoded is equal to $[1., 1., 0., 0., 0., 0., 0., 0.]$ which is distant from the 'center of gravity' by 1 (maximum value) in the two of the nine dimensions.

The encoder in this configuration is skewed in its performance to detect low count values that are present in the training process and overlook new values that are very different to them.

This problem might however be solved by fixing encoding of the empty string values. The initial analysis showed also that the paths should be normalised to start with the first subprocess of the msedge because it is always identical and does not introduce any information to the classification process. The values corresponding to the empty strings were manually adjusted to be equal 1 in the cases of exact match. Corrected data was once again used to in anomaly detection and the results can be found in the table xxx. Those values show improvement in the performance which is especially visible in the entry number x for the 'nu' value equal x.

The similarity encoder was also tested with the training on normalised paths without splitting them into components as well as only the value `'/msedge'` and an empty string. The performance for both is quite similar. The results are presented in the table xxx and xxx. Both of those approaches are capable of detecting outliers with higher success rate than the split path approach. It does however come with the cost in the false negative rate.

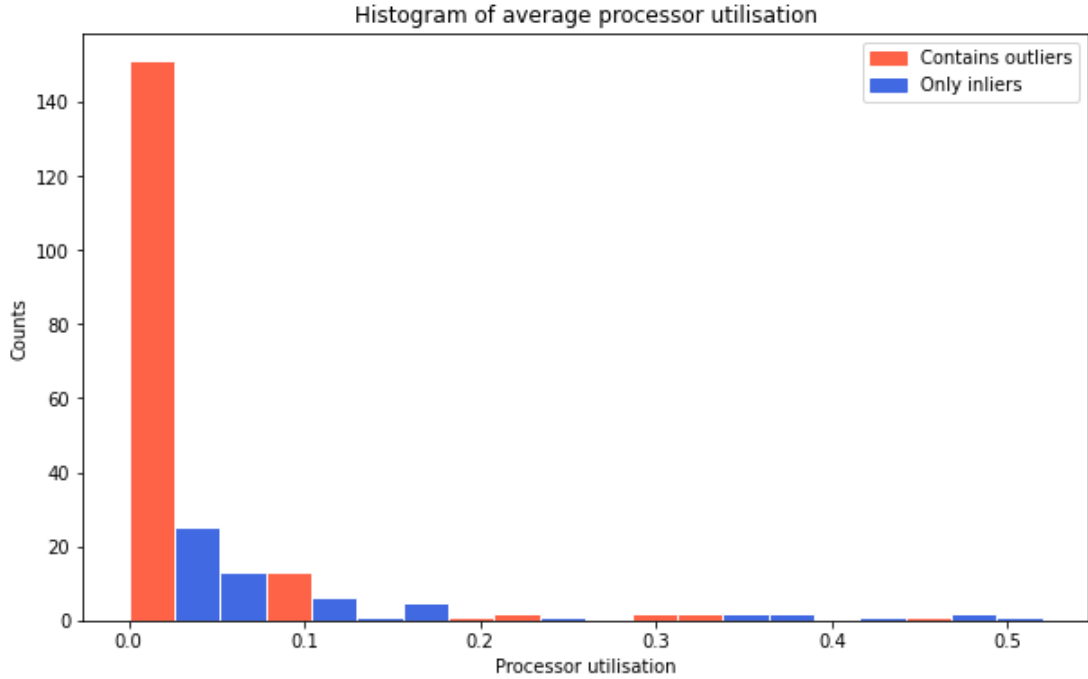

Figure 5.10: Distribution of the average processor utilisation.

5.3.3 Average processor utilisation

This feature is the easiest to analyze due to its quantitative nature and the fact that it is already normalised to the range between 0 and 1. Because of that it does not require virtually any preprocessing. The distribution of the values is presented on the histogram 5.10 with the bins containing anomaly values marked with red.

Obtained values show that anomaly detection with this feature may be feasible. It was attempted with the One Class SVM and the resulting receiver operating characteristic is presented in the figure 5.11 and proves the value of the feature. Its ease of utilisation makes it extra valuable.

The raw values of the anomaly detection performance can be accessed in the table x located in the appendix.

5.3.4 Combined performance

To further analyze the potential of the Event Trace for Windows data in the identification of anomalous processes spawned with zero day exploitation, all iden-

Figure 5.11: Distribution of the average processor utilisation.

tified valuable features were combined in a single experiment and their parameters were adjusted based on the previously drawn conclusions.

Chapter 6

Summary

There can be multiple conclusions drawn from the performed work. This chapter describes them in detail.

6.1 Security anomaly detection

6.2 Data sample

The dataset used in the experiments and analysis performed in the thesis can be significantly improved. Its main drawback is the available sample size. Gathering additional data would have positive impact on the reliability of the drawn conclusions. Additionally an improvement can be performed in the data gathering process. Simulated utilisation of the monitored system is a subpar system when compared to a deployment of the datagathering agents on the hosts of multiple real users. Obtaining the data from multiple sources would also allow for the cross analysis of the algorithms performance.

6.3 Browser intricacies

Browsers as programs are highly impacted by the actions of the users. They are capable of spawning multiple very distant in the purpose subprocesses. In the same session a single user can open start a notepad to view a text file as well as

starting an installation process which in turn starts a video game under the same umbrella of the browser subprocesses. This characteristic significantly complicates the anomaly detection process. This also suggests that methods and approaches developed for the application with the browsers may be highly effective when utilised with other outward facing programs like databases, web servers etc.

6.4 Unutilised data

Due to the limitations imposed in the data gathering process by the limited memory resources and its design multiple promising data features available in the Event Trace for Windows framework had to be left out of scope. Those include the information about the memory utilisation, hard drive input/output operations, system registry access, network send/receive and others. In the further research additional data should be gathered and analysed. This may require a design and implementation of the custom gathering framework.

6.5 Possible DLL hijacking detection

DLL hijacking is a technique of privilege escalation on Windows operating systems by hijacking the search order of the DLL loading. This allows for the execution of arbitrary code with the same rights as the exploited program. It can also be used as a persistence technique [2]. Some aspects of the gathered information were not used in the anomaly detection process but may be used to detect this specific type of attack.

Those include the "build time" and the "File version" of the loaded modules as well as their paths. Example of this data is presented in the figure x.
